

# Package: yaImpute (via r-universe)

September 9, 2024

**Type** Package

**Title** Nearest Neighbor Observation Imputation and Evaluation Tools

**Version** 1.0-35

**Date** 2024-09-09

**Description** Performs nearest neighbor-based imputation using one or more alternative approaches to processing multivariate data. These include methods based on canonical correlation analysis, canonical correspondence analysis, and a multivariate adaptation of the random forest classification and regression techniques of Leo Breiman and Adele Cutler. Additional methods are also offered. The package includes functions for comparing the results from running alternative techniques, detecting imputation targets that are notably distant from reference observations, detecting and correcting for bias, bootstrapping and building ensemble imputations, and mapping results.

**Depends** R (>= 4.0.0)

**Imports** grDevices, graphics, stats, utils

**Suggests** vegan, ccaPP, randomForest, gam, fastICA, parallel, gower

**Copyright** ANN library is copyright University of Maryland and Sunil Arya and David Mount. See file COPYRIGHTS for details.

**Maintainer** Jeffrey S. Evans <jeffrey\_evans@tnc.org>

**License** GPL (>= 2)

**URL** <https://github.com/jeffrejevans/yaImpute>

**BugReports** <https://github.com/jeffrejevans/yaImpute/issues>

**NeedsCompilation** yes

**Encoding** UTF-8

**RoxygenNote** 7.2.1

**Repository** <https://jeffrejevans.r-universe.dev>

**RemoteUrl** <https://github.com/jeffrejevans/yaimpute>

**RemoteRef** HEAD

**RemoteSha** 07f316a2642c720eff1ee7a82be5ca8d288b647d

 ann

*Approximate nearest neighbor search routines*

---

### Description

Given a set of reference data points  $S$ , ann constructs a kd-tree or box-decomposition tree (bd-tree) for efficient  $k$ -nearest neighbor searches.

**Usage**

```
ann(ref, target, k=1, eps=0.0, tree.type="kd",
    search.type="standard", bucket.size=1, split.rule="sl_midpt",
    shrink.rule="simple", verbose=TRUE, ...)
```

**Arguments**

<code>ref</code>	an $n \times d$ matrix containing the reference point set $S$ . Each row in <code>ref</code> corresponds to a point in $d$ -dimensional space.
<code>target</code>	an $m \times d$ matrix containing the points for which $k$ nearest neighbor reference points are sought.
<code>k</code>	defines the number of nearest neighbors to find. The default is $k=1$ .
<code>eps</code>	the $i^{th}$ nearest neighbor is at most $(1+eps)$ from true $i^{th}$ nearest neighbor, where $eps \geq 0$ . Specifically, the true (not squared) difference between the true $i^{th}$ and the approximation of the $i^{th}$ point is a factor of $(1+eps)$ . The default value of $eps=0$ is an exact search.
<code>tree.type</code>	the data structures kd-tree or bd-tree as quoted key words <i>kd</i> and <i>bd</i> , respectively. A brute force search can be specified with the quoted key word <i>brute</i> . If <i>brute</i> is specified, then all subsequent arguments are ignored. The default is the kd-tree.
<code>search.type</code>	either standard or priority search in the kd-tree or bd-tree, specified by quoted key words <i>standard</i> and <i>priority</i> , respectively. The default is the standard search.
<code>bucket.size</code>	the maximum number of reference points in the leaf nodes. The default is 1.
<code>split.rule</code>	is the strategy for the recursive splitting of those nodes with more points than the bucket size. The splitting rule applies to both the kd-tree and bd-tree. Splitting rule options are the quoted key words: <ol style="list-style-type: none"> <li>1. standard - standard kd-tree</li> <li>2. midpt - midpoint</li> <li>3. fair - fair-split</li> <li>4. midpt - sliding-midpoint (default)</li> <li>5. fair - fair-split rule</li> </ol> <p>See supporting documentation, reference below, for a thorough description and discussion of these splitting rules.</p>
<code>shrink.rule</code>	applies only to the bd-tree and is an additional strategy (beyond the splitting rule) for the recursive partitioning of nodes. This argument is ignored if <code>tree.type</code> is specified as <i>kd</i> . Shrinking rule options are quoted key words: <ol style="list-style-type: none"> <li>1. none - equivalent to the kd-tree</li> <li>2. simple - simple shrink (default)</li> <li>3. centroid - centroid shrink</li> </ol> <p>See supporting documentation, reference below, for a thorough description and discussion of these shrinking rules.</p>
<code>verbose</code>	if true, search progress is printed to the screen.
<code>...</code>	currently no additional arguments.

## Details

The ann function calls portions of the Approximate Nearest Neighbor Library, written by David M. Mount. All of the ann function arguments are detailed in the ANN Programming Manual found at <https://www.cs.umd.edu/~mount/ANN/>.

## Value

An object of class ann, which is a list with some or all of the following tags:

knnIndexDist	an $m \times 2k$ matrix. Each row corresponds to a target point in target and columns 1:k hold the ref matrix row indices of the nearest neighbors, such that column 1 index holds the ref matrix row index for the first nearest neighbor and column $k$ is the $k^{th}$ nearest neighbor index. Columns $k + 1:2k$ hold the Euclidean distance from the target to each of the $k$ nearest neighbors indexed in columns 1:k.
searchTime	total search time, not including data structure construction, etc.
k	as defined in the ann function call.
eps	as defined in the ann function call.
tree.type	as defined in the ann function call.
search.type	as defined in the ann function call.
bucket.size	as defined in the ann function call.
split.rule	as defined in the ann function call.
shrink.rule	as defined in the ann function call.

## Author(s)

Andrew O. Finley <finleya@msu.edu>

## Examples

```
## Make a couple of bivariate normal classes
rmvn <- function(n, mu=0, V = matrix(1))
{
  p <- length(mu)
  if(any(is.na(match(dim(V),p))))
    stop("Dimension problem!")
  D <- chol(V)
  matrix(rnorm(n*p), ncol=p) %*% D + rep(mu,rep(n,p))
}

m <- 10000

## Class 1.
mu.1 <- c(20, 40)
V.1 <- matrix(c(-5,1,0,5),2,2); V.1 <- V.1%*%t(V.1)
c.1 <- cbind(rmvn(m, mu.1, V.1), rep(1, m))

## Class 2.
```

```

mu.2 <- c(30, 60)
V.2 <- matrix(c(4,2,0,2),2,2); V.2 <- V.2%*%t(V.2)
c.2 <- cbind(rmvn(m, mu.2, V.2), rep(2, m))

## Class 3.
mu.3 <- c(15, 60)
V.3 <- matrix(c(5,5,0,5),2,2); V.3 <- V.3%*%t(V.3)
c.3 <- cbind(rmvn(m, mu.3, V.3), rep(3, m))

c.all <- rbind(c.1, c.2, c.3)
max.x <- max(c.all[,1]); min.x <- min(c.all[,1])
max.y <- max(c.all[,2]); min.y <- min(c.all[,2])

## Check them out.
plot(c.1[,1], c.1[,2], xlim=c(min.x, max.x), ylim=c(min.y, max.y),
     pch=19, cex=0.5,
     col="blue", xlab="Variable 1", ylab="Variable 2")
points(c.2[,1], c.2[,2], pch=19, cex=0.5, col="green")
points(c.3[,1], c.3[,2], pch=19, cex=0.5, col="red")

## Take a reference sample.
n <- 2000
ref <- c.all[sample(1:nrow(c.all), n),]

## Compare search times
k <- 10
## Do a simple brute force search.
brute <- ann(ref=ref[,1:2], target=c.all[,1:2],
             tree.type="brute", k=k, verbose=FALSE)
print(brute$searchTime)

## Do an exact kd-tree search.
kd.exact <- ann(ref=ref[,1:2], target=c.all[,1:2],
               tree.type="kd", k=k, verbose=FALSE)
print(kd.exact$searchTime)

## Do an approximate kd-tree search.
kd.approx <- ann(ref=ref[,1:2], target=c.all[,1:2],
                tree.type="kd", k=k, eps=100, verbose=FALSE)
print(kd.approx$searchTime)

## Takes too long to calculate for this many targets.
## Compare overall accuracy of the exact vs. approximate search
##knn.mode <- function(knn.indx, ref){
##  x <- ref[knn.indx,]
##  as.numeric(names(sort(as.matrix(table(x))[,1],
##                        decreasing=TRUE))[1])
##}

```

---

applyMask	<i>Removes neighbors that share (or not) group membership with targets.</i>
-----------	---

---

### Description

Some of the nearest neighbors found using `yai` or `newtargets` are removed using this function. This is possible when there are several reference observations for each target as is the case with  $k > 1$ . The function removes neighbor reference observations for a given target if the reference and target are in (a) the same group or (b) from different groups, depending on the method used. Group membership is identified for reference and target observations using two vectors, `refGroups` for references and `trgGroups` for targets. If the group membership code is the same for a reference and a target, then they are in the same group while different codes mean a lack of common group membership.

### Usage

```
applyMask(object, refGroups=NULL, trgGroups=NULL, method="removeWhenCommon", k=1)
```

### Arguments

<code>object</code>	an object of class <code>yai</code> .
<code>refGroups</code>	a vector, with length equal to the number of <i>reference</i> observations, of codes that indicate group membership.
<code>trgGroups</code>	a vector, with length equal to the number of <i>target</i> observations, of codes that indicate group membership. The data type and coding scheme of <code>refGroups</code> and <code>trgGroups</code> must be the same.
<code>method</code>	is the strategy used for removing neighbors from the object, as follows: <ol style="list-style-type: none"> <li>1. <code>removeWhenCommon</code> - remove neighbors where the group membership of a target is the same as the group membership of the near neighbor reference (that is, keep near neighbors if they are not in the same group).</li> <li>2. <code>keepWhenCommon</code> - keep near neighbors only when the reference is in the same group as the target (that is, remove near neighbors if they are not in the same group).</li> </ol>
<code>k</code>	the number of nearest neighbors to keep.

### Value

An object of class `yai`, that is a copy of the first argument with the following elements replaced:

<code>call</code>	the call.
<code>neiDstTrgs</code>	a matrix of distances between a target (identified by its row name) and the <code>k</code> references. There are <code>k</code> columns.
<code>neiIdsTrgs</code>	a matrix of reference identifications that correspond to <code>neiDstTrgs</code> .
<code>neiDstRefs</code>	set <code>NULL</code> as if <code>noRefs=TRUE</code> in the original call to <code>yai</code> .
<code>neiIdsRefs</code>	set <code>NULL</code> as if <code>noRefs=TRUE</code> in the original call to <code>yai</code> .

noRefs            set TRUE regardless of original value.  
k                 the value of k.

[yai newtargets](#)

### Examples

```
require (yaImpute)

data(iris)

# build a base case, there are no targets,
#   turn off getting references neighbors.
mal <- yai(x=iris[,-5],method="mahalanobis", noRefs = TRUE)

# create a new data, just a copy of the old with new row names.
iris2 <- iris
rownames(iris2) <- paste0("new.",rownames(iris))

# do an imputation with k=55
m55 <- newtargets(mal,newdata=iris2,k=55)

# get the 2 closest where the species codes don't match by
# removing neighbors when the ref group membership is
# in common with the target group membership (same species),
# thereby forcing neighbors to be from different species.

# in this case, the groups are species codes.

applyMask(m55,refGroups=iris$Species,trgGroups=iris2$Species,
          method="removeWhenCommon",k=2)

# get the 2 closest where the species codes do match by
# removing neighbors when the ref group membership is
# different than the target group membership (different species),
# thereby forcing neighbors to be from the same species (this
# is generally true anyway using the iris data).

applyMask(m55,iris$Species,trgGroups=iris2$Species,
          method="keepWhenCommon",k=2)
```

---

AsciiGridImpute	<i>Imputes/Predicts data for Ascii Grid maps</i>
-----------------	--

---

### Description

AsciiGridImpute finds nearest neighbor *reference* observations for each point in the input grid maps and outputs maps of selected Y-variables in a corresponding set of output grid maps.

AsciiGridPredict applies a predict function to each point in the input grid maps and outputs maps of the prediction(s) in corresponding output grid maps (see Details).

One row of each grid map is read and processed at a time thereby avoiding the need to build huge objects in R that would be necessary if all the rows of all the maps were processed together.

### Usage

```
AsciiGridImpute(object, xfiles, outfiles, xtypes=NULL, ancillaryData=NULL,
                ann=NULL, lon=NULL, lat=NULL, rows=NULL, cols=NULL,
                nodata=NULL, myPredFunc=NULL, ...)
```

```
AsciiGridPredict(object, xfiles, outfiles, xtypes=NULL, lon=NULL, lat=NULL,
                 rows=NULL, cols=NULL, nodata=NULL, myPredFunc=NULL, ...)
```

### Arguments

- |          |   |
|----------|---|
| object   | An object of class <code>yai</code> , any object for which a <code>predict</code> function is defined, or an object that is passed to a predict function you define using argument <code>myPredFunc</code> . See Details.   |
| xfiles   | A <code>list</code> of input file names where there is one grid file for each X-variable. List elements must be given the same names as the X-variables they correspond with and there must be one file for each X-variable used when object was built.   |
| outfiles | One of these two forms: <ol style="list-style-type: none"> <li>1. A file name that is understood to correspond to the single prediction returned by the generic <code>predict</code> function related to object or returned by <code>myPredFunc</code>. This form only applies to <code>AsciiGridPredict</code>, when the object is not class <code>yai</code>.</li> <li>2. A <code>list</code> of output file names where there is one grid file for each <i>desired</i> output variable. While there may be many variables predicted for object, only those for which an output grid is desire need to be specified. Note that some predict functions return data frames, some return a single vector, and often what is returned depends on the value of arguments passed to predict. In addition to names of the predicted variables, the following two special names can be coded when the object class is <code>yai</code>: For <code>distance="filename"</code> a map of the distances is output and if <code>useid="filename"</code> a map of integer indices to row numbers of the reference observations is output. When the predict function returns a vector, an additional special name of <code>predict="filename"</code> can be used.</li> </ol> |

xtypes	A list of data type names that corresponds exactly to data type of the maps listed in xfiles. Each value can be one of: "logical", "integer", "numeric", "character". If NULL, or if a type is missing for a member of xfiles, type "numeric" is used. See Details if you used factors as predictors.
ancillaryData	A data frame of Y-variables that may not have been used in the original call to <code>yai</code> . There must be one row for each reference observation, no missing data, and row names must match those used in the original reference observations.
ann	if NULL, the value is taken from object. When TRUE, <code>ann</code> is used to find neighbors, and when FALSE a slow exact search is used (ignored for when method <code>randomForest</code> is used when the original <code>yai</code> object was created).
lon	if NULL, the value of <code>cols</code> is used. Otherwise, a 2-element vector given the range of longitudes (horizontal distance) desired for the output.
lat	if NULL, the value of <code>rows</code> is used. Otherwise, a 2-element vector given the range of latitudes (vertical distance) desired for the output.
rows	if NULL, all rows from the input grids are used. Otherwise, <code>rows</code> is a 2-element vector given the rows desired for the output. If the second element is greater than the number of rows, the header value <code>YLLCORNER</code> in the output is adjusted accordingly. Ignored if <code>lon</code> is specified.
cols	if NULL, all columns from the input grids are used. Otherwise, <code>cols</code> is a 2-element vector given the columns desired for the output. If the first element is greater than one, the header value <code>XLLCORNER</code> in the output is adjusted accordingly. Ignored if <code>lat</code> is specified.
nodata	the <code>NODATA_VALUE</code> for the output. If NULL, the value is taken from the input grids.
myPredFunc	called by <code>AsciiGridPredict</code> to predict output using the object and <code>newdata</code> from the <code>xfiles</code> . Two arguments are passed by <code>AsciiGridPredict</code> to this function, the first is the value of object and the second is a data frame of the new predictor variables created for each row of data from your input maps. If NULL, the generic <code>predict</code> function is called for object.
...	passed to <code>myPredFunc</code> , <code>predict</code> , or <code>impute</code> .

## Details

The input maps are assumed to be AsciiGrid maps with 6-line headers containing the following tags: `NCOLS`, `NROWS`, `XLLCORNER`, `YLLCORNER`, `CELLSIZE` and `NODATA_VALUE` (case insensitive). The headers should be identical for all input maps, a warning is issued if they are not. It is critical that `NODATA_VALUE` is the same on all input maps.

The function builds data frames from the input maps one row at a time and builds predictions using those data frames as *newdata*. Each row of the input maps is processed in sequence so that the entire maps are not stored in memory. The function works by opening all the input and reads one line (row) at a time from each. The output file(s) are created one line at time as the input maps are processed.

Use `AsciiGridImpute` for objects builds with `yai`, otherwise use `AsciiGridPredict`. When `AsciiGridPredict` is used, the following rules apply. First, when `myPredFunc` is not null it is called with the arguments `object`, `newdata`, ... where the new data is the data frame built from

the input maps, otherwise the generic `predict` function is called with these same arguments. When `object` and `myPredFunc` are both `NULL` a copy `newdata` used as the prediction. This is useful when `lat`, `lon`, `rows`, or `cols` are used in to subset the maps.

The `NODATA_VALUE` is output for every `NODATA_VALUE` found on any grid cell on any one of the input maps (the `predict` function is not called for these grid cells). `NODATA_VALUE` is also output for any grid cell where the `predict` function returns an `NA`.

If factors are used as `X`-variables in `object`, the levels found the map data are checked against those used in building the object. If new levels are found, the corresponding output map grid point is set to `NODATA_VALUE`; the `predict` function is not called for these cells as most `predict` functions will fail in these circumstances. Checking on factors depends on `object` containing a meaningful member named `xlevels`, as done for objects produced by [lm](#).

Asciigrid maps do not contain character data, only numbers. The numbers in the maps are matched the `xlevels` by subscript (the first entry in a level corresponds to the numeric value 1 in the Asciigrid maps, the second to the number 2 and so on). Care must be taken by the user to insure that the coding scheme used in building the maps is identical to that used in building the object. See [Value](#) for information on how you can check the matching of these codes.

## Value

An `invisible` list containing the following named elements:

<code>unexpectedNAs</code>	A data frame listing the map row numbers and the number of <code>NA</code> values generated by the <code>predict</code> function for each row. If none are generated for a row the row is not reported, if none are generated for any rows, the data frame is <code>NULL</code> .
<code>illegalLevels</code>	A data frame listing levels found in the maps that were not found in the <code>xlevels</code> for the object. The row names are the illegal levels, the column names are the variable names, and the values are the number of grid cells where the illegal levels were found.
<code>outputLegend</code>	A data frame showing the relationship between levels in the output maps and those found in <code>object</code> . The row names are level index values, the column names are variable names, and the values are the levels. <code>NULL</code> if no factors are output.
<code>inputLegend</code>	A data frame showing the relationship between levels found in the input maps and those found in <code>object</code> . The row names are level index values (this function assumes they correspond to numeric values on the maps), the column names are variable names, and the values are the levels. <code>NULL</code> if no factors are input. This information is consistent with that in <code>xlevels</code> .

---

bestVars	<i>Computes the number of best X-variables</i>
----------	--

---

### Description

The number of *best* variables is estimated by finding an apparent inflection point in the relationship between the generalized root mean square distance (see [grmsd](#) and the number of X-variables.

### Usage

```
bestVars(obj, nbest=NULL)
```

### Arguments

obj	an object create by <a href="#">varSelection</a>
nbest	number of variables designated as the best; if null the number is estimated

### Value

An character vector of variable names in decreasing order of importance.

---

buildConsensus	<i>Finds the consensus imputations among a list of yai objects</i>
----------------	--

---

### Description

Several objects of class `yai` are combined into a new object forming a consensus among the many. The intention is that the many would be formed by running `yai` several times with `bootstrap=TRUE` or by varying other options.

### Usage

```
buildConsensus(reps, noTrgs=FALSE, noRefs=FALSE, k=NULL)
```

### Arguments

<code>reps</code>	a list of objects class <code>yai</code> .
<code>noTrgs</code>	If TRUE neighbor relationships for target observations are not merged.
<code>noRefs</code>	If TRUE neighbor relationships for reference observations are not merged.
<code>k</code>	If not specified, the minimum value of k among the objects is used.

### Value

An object of class `yai`

### Author(s)

Nicholas L. Crookston <ncrookston.fs@gmail.com>  
John Coulston <jcoulston@fs.fed.us>

`yai`

### Examples

```
require(yaImpute)
data(iris)

set.seed(123)

# form some test data, y's are defined only for reference
# observations.
refs=sample(rownames(iris),50)
x <- iris[,1:2]      # Sepal.Length Sepal.Width
y <- iris[refs,3:4] # Petal.Length Petal.Width

reps <- replicate(20, yai(x=x,y=y,method="msn",bootstrap=TRUE,k=2),
```

```

                                simplify=FALSE)
buildConsensus(reps)

```

---

compare.yai	<i>Compares different k-NN solutions</i>
-------------	--

---

### Description

Provides a convenient display of the root mean square differences (see [rmsd.yai](#)) or correlations (see [cor.yai](#)) between observed and imputed values for each of several imputations. Each column of the returned data frame corresponds to an imputation result and each row corresponds to a variable.

### Usage

```
compare.yai(..., ancillaryData=NULL, vars=NULL, method="rmsd", scale=TRUE)
```

### Arguments

...	a list of objects created by <a href="#">yai</a> or <a href="#">impute.yai</a> that you wish to compare.
ancillaryData	a data frame that defines new variables, passed to <a href="#">impute.yai</a> .
vars	a list of variable names you want to include; if NULL all available variables are included.
method	when <i>rmsd</i> is specified, the comparison is based on root mean square differences between observed and imputed, and when <i>cor</i> is specified, the comparison is based on correlations between observed and imputed.
scale	passed to <a href="#">rmsd.yai</a>

### Value

A data.frame of class c("compare.yai", "data.frame"), where the columns are the names of the ...-arguments and the rows are a union of variable names. NA's are returned when the variables are factors. The scale values (if used) are returned as an attribute (all if some are different than others, a warning is issued).

```

require(yaImpute)

data(iris)

# form some test data
refs=sample(rownames(iris),50)
x <- iris[,1:2]      # Sepal.Length Sepal.Width
y <- iris[refs,3:4] # Petal.Length Petal.Width

# build yai objects using 2 methods
msn <- yai(x=x,y=y)
mal <- yai(x=x,y=y,method="mahalanobis")

# compare the y variables
compare.yai(msn,mal)

# compare the all variables in iris
compare.yai(msn,mal,ancillaryData=iris) # Species is a factor, no comparison is made

```

---

cor.yai

*Correlation between observed and imputed*

---

**Description**

Computes the correlation between observed and imputed values for each observation that has both.

**Usage**

```
cor.yai (object, vars=NULL, ...)
```

**Arguments**

object	an object created by <a href="#">yai</a> or <a href="#">impute.yai</a> .
vars	a list of variables names you want to include, if NULL all available variables are included.
...	passed to called methods (not currently used)

**Details**

The correlations are computed using [cor.yai](#). For data imputation, such correlations are likely not appropriate (Stage and Crookston 2007).

**Value**

A data frame with the row names as vars and the column as cor.

 correctBias

---

*Correct bias by selecting different near neighbors*

---

**Description**

Change the neighbor selections in a [yai](#) object such that bias (if any) in the average value of an *expression* of one or more variables is reduced to be within a defined confidence interval.

**Usage**

```
correctBias(object, trgVal, trgValCI=NULL, nStdev=1.5, excludeRefIds=NULL, trace=FALSE)
```

**Arguments**

object	an object of class <a href="#">yai</a> with $k > 1$ .
trgVal	an <a href="#">expression</a> defining a variable or combination of variables that is applied to each member of the population (see details). If passed as a character string it is coerced into an expression. The expression can refer to one or more X- and Y-variables defined for the reference observations.
trgValCI	The confidence interval that should contain the mean( <a href="#">trgVal</a> ). If the mean falls within this interval, the problem is solved. If NULL, the interval is based on nStdev.
nStdev	the number of standard deviations in the vector of values used to compute the confidence interval when one is computed, ignored if <a href="#">trgValCI</a> is not NULL.
excludeRefIds	identities of reference observations to exclude from the population, if coded as "all" then all references are excluded (see details).
trace	if TRUE, detailed output is produced.

## Details

Imputation as it is defined in `yaImpute` can yield biased results. Lets say that you have a collection of reference observations that happen to be selected in a non-biased way among a population. In this discussion, *population* is a finite set of all individual sample units of interest; the reference plus target observations often represent this population (but this need not be true, see below). If the average of a measured attribute is computed from this random sample, it is an unbiased estimate of the true mean.

Using `yai`, while setting  $k=1$ , values for each of several attributes are imputed from a single reference observation to a target observation. Once the imputation is done over all the target observations, an average of any one measured attribute can be computed over all the observations in the population. There is no guarantee that this average will be within a pre-specified confidence interval.

Experience shows that despite any lack of guarantee, the results are accurate (not biased). This tends to hold true when the reference data contains samples that cover the variation of the targets, even when they are not a random sample, and even if some of the reference observations are from sample units that are outside the target population.

Because there is no guarantee, and because the reference observations might profitably come from sample units beyond those in the population (so as to insure all kinds of targets have a matching reference), it is necessary to test the imputation results for bias. If bias is found, it would be helpful to do something to correct it.

The `correctBias()` function is designed to check for, and correct discovered bias by selecting alternative nearby reference observations to be imputed to targets that contribute to the bias. The idea is that even if one reference is closest to a target, its attribute(s) of interest might be greater (or less) than the mean. An alternative neighbor, one that may be almost as close, might reduce the overall bias if it were used instead. If this is the case, `correctBias()` switches the neighbor selections. It makes as many switches as it can until the mean among the population targets falls within the specified confidence interval. There is no guarantee that the goal will be met.

The details of the method are:

1. An attribute of interest is established by naming one in the call with argument `tarVal`. Note that this can be a simple variable name enclosed in quotations marks or it can be an [expression](#) of one or more variables. If the former, it is converted into an expression that is executed in the environment of the reference observations (both the X- and Y-variables). A confidence interval is computed for this value under the assumption that the reference observations are an unbiased sample of the target population. This may not be the case. Regardless, a confidence interval is *necessary* and it can alternatively be supplied using `trgValCI`.
2. One of several possible passes through the data are taken to find neighbor switches that will result in the bias being corrected. A pass includes computing the attribute of interest by applying the expression to values imputed to all the targets, under the assumption that the next neighbor is used in place of the currently used neighbor. This computation results in a vector with one element for each target observation that measures the contribution toward reducing the bias that would be made if a switch were made. The target observations are then ordered into increasing order of how much the distance from the currently selected reference would increase if the switch were to take

place. Enough switches are made in this order to correct the bias. If the bias is not corrected by the first pass, another pass is done using the next neighbor(s). The number of possible passes is equal to  $k-1$  where  $k$  is set in the original call to `yai`. Note that switches are made among targets only, and never among reference observations that may make up the population. That is, reference observations are always left to represent themselves with  $k=1$ .

3. Here are details of the argument `excludeRefIds`. When computing the mean of the attribute of interest (using the expression), `correctBias()` must know which observations represent the population. Normally, all the target observations would be in this set, but perhaps not all of the reference observations. When `excludeRefIds` is left NULL, the population is made of all reference and all target observations. Reference observations that should be left out of the calculations because they are not part of the population can be specified using the `excludeRefIds` argument as a vector of character strings identifying the rownames to leave out, or a vector of row numbers that identify the row numbers to leave out. If `excludeRefIds="all"`, all reference observations are excluded.

### Value

An object of class `yai` where  $k = 1$  and the neighbor selections have been changed as described above. In addition, the `call` element is changed to show both the original call to `yai` and the call to this function. A new list called `biasParameters` is added to the `yai` object with these tags:

<code>trgValCI</code>	the target CI.
<code>curVal</code>	the value of the bias that was achieved.
<code>npasses</code>	the number of passes through the data taken to achieve the result.
<code>oldk</code>	the old value of $k$ .

### Examples

```
data(iris)

set.seed(12345)

# form some test data
refs=sample(rownames(iris),50)
x <- iris[,1:3]      # Sepal.Length Sepal.Width Petal.Length
y <- iris[refs,4:5] # Petal.Width Species

# build an msn run, first build dummy variables for species.

sp1 <- as.integer(iris$Species=="setosa")
```

```

sp2 <- as.integer(iris$Species=="versicolor")
y2 <- data.frame(cbind(iris[,4],sp1,sp2),row.names=row.names(iris))
y2 <- y2[refs,]

names(y2) <- c("Petal.Width","Sp1","Sp2")

# find 5 refernece neighbors for each target
msn <- yai(x=x,y=y2,method="msn",k=5)

# check for and correct for bias in mean "Petal.Width". Neighbor
# selections will be changed as needed to bring the imputed values
# into line with the CI. In this case, no changes are made (npasses
# returns as zero).

msnCorr = correctBias(msn,trgVal="Petal.Width")
msnCorr$biasParameters

```

---

ensembleImpute	<i>Computes the mean, median, or mode among a list of impute.yai objects</i>
----------------	--

---

## Description

Several objects of class `impute.yai` or `yai` are combined by computing the mean, median, or mode of separate, individual imputations. The intention is that the members of the first argument would be formed by running `yai` several times with `bootstrap=TRUE` or by varying other options.

## Usage

```
ensembleImpute(imputes, method="mean",...)
```

## Arguments

imputes	a list of objects class <code>impute.yai</code> or <code>yai</code> . Function <code>impute.yai</code> is called for list members where the class is <code>yai</code> .
method	when "mean", the continuous variables are averaged using mean, otherwise the median is used. Mode is always used for character data (generally the case for factors).
...	passed to <code>impute.yai</code> .

## Value

An object of class `c("impute.yai", "data.frame")`, see `impute.yai`. The attributes of the `data.frame` include the following:

1. `sd` - A `data.frame` of standard deviations for continuous variables if there are any. The columns are not reported if the standard deviation is zero for all observations which is typically true of "observed" values.

2. N - the number of replications used to compute the corresponding data; reported only if the number differs from the total number of replications. This will be the case when `bootstrap`, `sampleVar`, or both are used in `yai`.
3. methods - the method used for each variable.

# form some test data, y's are defined only for reference
# observations.
refs=sample(rownames(iris),50)
x <- iris[,1:2]      # Sepal.Length Sepal.Width
y <- iris[refs,3:4] # Petal.Length Petal.Width

reps <- replicate(10, yai(x=x,y=y,method="msn",bootstrap=TRUE,k=2),
                  simplify=FALSE)

ensembleImpute(reps,ancillaryData=iris)
```

---

errorStats

*Compute error components of k-NN imputations*

---

**Description**

Error properties of estimates derived from imputation differ from those of regression-based estimates because the two methods include a different mix of error components. This function computes a partitioning of error statistics as proposed by Stage and Crookston (2007).

**Usage**

```
errorStats(mahal, ..., scale=FALSE, pzero=0.1, plg=0.5, seeMethod="lm")
```

**Arguments**

mahal	An object of class <code>yai</code> computed with <code>method="mahalanobis"</code> .
...	Other objects of class <code>yai</code> for which statistics are desired. All objects should be for the same data and variables used for the first argument.
scale	When TRUE, the errors are scaled by their respective standard deviations.
pzero	The lower tail p-value used to pick <i>reference</i> observations that are zero distance from each other (used to compute <code>rmmsd0</code> ).
plg	The upper tail p-value used to pick <i>reference</i> observations that are substantially distant from each other (used to compute <code>rmsdlg</code> ).
seeMethod	Method used to compute SEE: <code>seeMethod="lm"</code> uses <code>lm</code> and <code>seeMethod="gam"</code> uses <code>gam</code> . In both cases, the model formula is a simple linear combination of the X-variables.

**Details**

See <https://academic.oup.com/forestscience/article/53/1/62/4604364>

**Value**

A list that contains several data frames. The column names of each are a combination of the name of the object used to compute the statistics and the name of the statistic. The rownames correspond to the Y-variables from the first argument. The data frame names are as follows:

common	statistics used to compute other statistics.
name of first argument	error statistics for the first <code>yai</code> object.
names of ... arguments	error statistics for each of the remaining <code>yai</code> objects, if any.
see	standard error of estimate for individual regressions fit for corresponding Y-variables.
rmmsd0	root mean square difference for imputations based on <code>method="mahalanobis"</code> (always based on the first argument to the function).
mlf	square root of the model lack of fit: $\sqrt{see^2 - (rmmsd0^2/2)}$ .
rmsd	root mean square error.
rmsdlg	root mean square error of the observations with larger distances.
sei	standard error of imputation $\sqrt{rmsd^2 - (rmmsd0^2/2)}$ .
dstc	distance component: $\sqrt{rmsd^2 - rmmsd0^2}$ .

Note that unlike Stage and Crookston (2007), all statistics reported here are in the natural units, not squared units.

---

foruse

*Report a complete imputation*

---

## Description

Provides a matrix of all observations with the reference observation identification best used to represent it, followed by the distance.

## Usage

```
foruse(object,kth=NULL,method="kth",targetsOnly=FALSE)
```

**Arguments**

object	an object created by <a href="#">yai</a>
kth	when NULL (and method="kth"), the best pick is reported (a reference observation represents itself), otherwise the kth neighbor is picked.
method	the method used to select references to represent observations, as follows: kth: the <i>kth</i> nearest neighbor is picked; random: for each observation, the value of <i>kth</i> is selected at random from the 1 to k neighbors (1 to kth if is kth specified); randomWeighted: $1/(1+d)$ is used as a probability weight factor in selecting the value of <i>kth</i> , where d is the distance..
targetsOnly	when is TRUE, reporting of references is not done.

**Author(s)**

Nicholas L. Crookston <ncrookston.fs@gmail.com>  
Andrew O. Finley <finleya@msu.edu>

**Examples**

```
require(yaImpute)

data(iris)

# form some test data
set.seed(1234)
refs=sample(rownames(iris),50)
x <- iris[,1:3]      # Sepal.Length Sepal.Width Petal.Length
y <- iris[refs,4:5] # Petal.Width Species

# build a yai object using mahalanobis
mal <- yai(x=x,y=y,method="mahalanobis",k=3)

foruse(mal) # for references, use is equal to the rowname
foruse(mal,kth=1) # for references, use is an row to the kth reference.

# get all the choices:
cbind(foruse(mal),foruse(mal,kth=1),foruse(mal,kth=2),foruse(mal,kth=3))
```

## Description

Computes the root mean square distance between predicted and corresponding observed values in an orthogonal multivariate space. This value is the mean Mahalanobis distance between observed and imputed values in a space defined by observations and variables were observed and predicted values are defined. The statistic provides a way to compare imputation (or prediction) results. While it is designed to work with imputation, the function can be used with objects that inherit from `lm` or with matrices and data frames that follow the column naming convention described in the details.

## Usage

```
grmsd(..., ancillaryData=NULL, vars=NULL, wts=NULL, rtnVectors=FALSE, imputeMethod="closest")
```

## Arguments

<code>...</code>	objects created by any combination of <code>yai</code> , <code>impute.yai</code> , <code>ensembleImpute</code> , <code>buildConsensus</code> , <code>lm</code> and data frames or matrices that follow the column naming convention described in the details below. If an object is of class <code>yai</code> , a call to <code>impute.yai</code> is generated internally.
<code>ancillaryData</code>	a data frame that defines variables, passed to <code>impute.yai</code> .
<code>vars</code>	a list of variable names you want to include; if <code>NULL</code> all available variables are included (note that if <code>impute.yai</code> the <i>Y</i> -variables are returned when <code>vars=NULL</code> ).
<code>wts</code>	A vector of weights used to compute the mean distances, see details below.
<code>rtnVectors</code>	The vectors of individual distances are returned (see <code>Value</code> ) rather than the mean Mahalanobis distance.
<code>imputeMethod</code>	passed as method to <code>impute.yai</code> .

## Details

This function is designed to compute the root mean square distance between observed and predicted observations over several variables at once. It is the Mahalanobis distance between observed and predicted but the name emphasizes the similarities to root mean square difference (or error, see `rmsd`). Here are some notable characteristics.

1. In the univariate case this function returns the same value as `rmsd` with `scale=TRUE`. In that case the root mean square difference is computed after `scale` has been called on the variable.
2. Like `rmsd`, `grmsd` is zero if the imputed values are exactly the same as the observed values over all variables.
3. Like `rmsd`, `grmsd` is  $\sim 1.0$  when the mean of each variable is imputed in place of a near neighbor (it would be exactly 1.0 if the maximum likelihood estimate of the covariance were used rather than the unbiased estimate – it approaches 1 as  $n$  gets large.) This situation corresponds to regression where the slope is zero. It indicates that the imputation error is, over all, the same as it would be if the means of the variables were imputed rather than near neighbors (it does not signal that the means were imputed).
4. Like `rmsd`, values of `grmsd`  $> 1.0$  indicate that, on average, the errors in the imputation are greater than they would be if the mean of the corresponding variables were imputed for each observation.

- Note that individual `rmsd` values can be computed even when the variance of the variable is zero. In contrast, `grmsd` can only be computed in the situation where the observed data matrix is full rank. Rank is determined using `qr` and columns are removed from the analysis to create this condition if necessary (with a warning).

Observed and predicted are matched using the column names. Column names that have ".o" are matched to those that do not. Columns that do not have matching observed and imputed (predicted) values are ignored.

Several objects may be passed as "...". Function `impute.yai` is called for any objects that were created by `yai`; `ancillaryData` and `vars` are passed to `impute.yai` when it is used.

When objects inherit from `lm`, a suitable matrix is formed using by calling the `predict` and `resid` functions.

Factors, if found, are removed (with a warning).

When argument `wts` is defined there must be one value for each pair of observed and predicted variables. If the values are named (preferred), then the names are matched to the names of predicted variables (no ".o" suffix). The matched values effectively scale the axes in which distances are computed. When this is done, the resulting distances are not Mahalanobis distances.

## Value

When `rtnVectors=FALSE`, a sorted named vector of mean distances is returned; the names are taken from the arguments.

When `rtnVectors=TRUE` the function returns vectors of distances, sorted and named as done when this argument is `FALSE`.

```

---

impute.yai

*Impute variables from references to targets*

---

## Description

Imputes the observation for variables from a *reference* observation to a *target* observation. Also, imputes a value for a *reference* from other *references*. This practice is useful for validation (see [yai](#)). Variables not available in the original data may be imputed using argument `ancillaryData`.

## Usage

```

## S3 method for class 'yai'
impute(object,ancillaryData=NULL,method="closest",
        method.factor=method,k=NULL,vars=NULL,
        observed=TRUE,...)

```

**Arguments**

object	an object of class <code>yai</code> .
ancillaryData	a data frame of variables that may not have been used in the original call to <code>yai</code> . There must be one row for each reference observation, no missing data, and row names must match those used in the reference observations.
method	the method used to compute the imputed values for continuous variables, as follows: closest: use the single neighbor that is closest (this is the default and is always used when $k=1$ ); mean: the mean of the $k$ neighbors is taken; median: the median of the $k$ neighbors is taken; dstWeighted: a weighted mean is taken over the $k$ neighbors where the weights are $1/(1+d)$ .
method.factor	the method used to compute the imputed values for factors, as follows: closest: use the single neighbor that is closest (this is the default and is always used when $k=1$ ); mean or median: actually is the <i>mode</i> —it is the factor level that occurs the most often among the $k$ neighbors; dstWeighted: a <i>mode</i> where the count is the sum of the weights ( $1/(1+d)$ ) rather than each having a weight of 1.
k	the number neighbors to use in averages, when NULL all present are used.
vars	a character vector of variables to impute, when NULL, the behaviour depends on the value of <code>ancillaryData</code> : when it is NULL, the Y-variables are imputed and otherwise all present in <code>ancillaryData</code> are imputed.
observed	when TRUE, columns are created for <i>observed</i> values (those from the <i>target</i> observations) as well as imputed values (those from the <i>reference</i> observations).
...	passed to other methods, currently not used.

**Value**

An object of class `c("impute.yai", "data.frame")`, with rownames identifying observations and column names identifying variables. When `observed=TRUE` additional columns are created with a suffix of `.o`.

NA's fill columns of observed values when no corresponding value is known, as in the case for Y-variables from *target* observations.

Scale factors for each variable are returned as an attribute (see `attributes`).

---

MoscowMtStJoe

*Moscow Mountain and St. Joe Woodlands (Idaho, USA) Tree and Li-DAR Data*

---

**Description**

Data used to compare the utility of discrete-return light detection and ranging (LiDAR) data and multispectral satellite imagery, and their integration, for modeling and mapping basal area and tree density across two diverse coniferous forest landscapes in north-central Idaho, USA.

**Usage**

```
data(MoscowMtStJoe)
```

**Format**

A data frame with 165 rows and 64 columns:

Ground based measurements of trees:

- ABGR\_BA - Basal area ( $m^2/ha$ ) of ABGR
- ABLA\_BA - Basal area ( $m^2/ha$ ) of ABLA
- ACGL\_BA - Basal area ( $m^2/ha$ ) of ACGL

- BEOC\_BA - Basal area ( $m^2/ha$ ) of BEOC
- LAOC\_BA - Basal area ( $m^2/ha$ ) of LAOC
- PICO\_BA - Basal area ( $m^2/ha$ ) of PICO
- PIEN\_BA - Basal area ( $m^2/ha$ ) of PIEN
- PIMO\_BA - Basal area ( $m^2/ha$ ) of PIMO
- PIPO\_BA - Basal area ( $m^2/ha$ ) of PIPO
- POBA\_BA - Basal area ( $m^2/ha$ ) of POBA
- POTR\_BA - Basal area ( $m^2/ha$ ) of POTR
- PSME\_BA - Basal area ( $m^2/ha$ ) of PSME
- SAEX\_BA - Basal area ( $m^2/ha$ ) of SAEX
- THPL\_BA - Basal area ( $m^2/ha$ ) of THPL
- TSHE\_BA - Basal area ( $m^2/ha$ ) of TSHE
- TSME\_BA - Basal area ( $m^2/ha$ ) of TSME
- UNKN\_BA - Basal area ( $m^2/ha$ ) of unknown species
- Total\_B - Basal area ( $m^2/ha$ ) total over all species
- ABGR\_TD - Trees per ha of ABGR
- ABLA\_TD - Trees per ha of ABLA
- ACGL\_TD - Trees per ha of ACGL
- BEOC\_TD - Trees per ha of BEOC
- LAOC\_TD - Trees per ha of LAOC
- PICO\_TD - Trees per ha of PICO
- PIEN\_TD - Trees per ha of PIEN
- PIMO\_TD - Trees per ha of PIMO
- PIPO\_TD - Trees per ha of PIPO
- POBA\_TD - Trees per ha of POBA
- POTR\_TD - Trees per ha of POTR
- PSME\_TD - Trees per ha of PSME
- SAEX\_TD - Trees per ha of SAEX
- THPL\_TD - Trees per ha of THPL
- TSHE\_TD - Trees per ha of TSHE
- TSME\_TD - Trees per ha of TSME
- UNKN\_TD - Trees per ha of unknown species
- Total\_T - Trees per ha total over all species

Geographic Location, Slope and Aspect:

1. EASTING - UTM (Zone 11) easting at plot center
2. NORTHING - UTM (Zone 11) northing at plot center
3. ELEVATION - Mean elevation (m) above sea level over plot

4. SLPMEAN - Mean slope (percent) over plot
5. ASPMEAN - Mean aspect (degrees) over plot

Advanced Land Imager (ALI):

1. B1MEAN - Mean of 30 m ALI band 1 pixels intersecting plot
2. B2MEAN - Mean of 30 m ALI band 2 pixels intersecting plot
3. B3MEAN - Mean of 30 m ALI band 3 pixels intersecting plot
4. B4MEAN - Mean of 30 m ALI band 4 pixels intersecting plot
5. B5MEAN - Mean of 30 m ALI band 5 pixels intersecting plot
6. B6MEAN - Mean of 30 m ALI band 6 pixels intersecting plot
7. B7MEAN - Mean of 30 m ALI band 7 pixels intersecting plot
8. B8MEAN - Mean of 30 m ALI band 8 pixels intersecting plot
9. B9MEAN - Mean of 30 m ALI band 9 pixels intersecting plot
10. PANMEA - Mean of 10 m PAN band pixels intersecting plot
11. PANSTD - Standard deviation of 10 m PAN band pixels intersecting plot

LiDAR Intensity:

1. INTMEAN - Mean of 2 m intensity pixels intersecting plot
2. INTSTD - Standard deviation of 2 m intensity pixels intersecting plot
3. INTMIN - Minimum of 2 m intensity pixels intersecting plot
4. INTMAX - Maximum of 2 m intensity pixels intersecting plot

LiDAR Height:

1. HTMEAN - Mean of 6 m height pixels intersecting plot
2. HTSTD - Standard deviation of 6 m height pixels intersecting plot
3. HTMIN - Minimum of 6 m height pixels intersecting plot
4. HTMAX - Maximum of 6 m height pixels intersecting plot

LiDAR Canopy Cover:

1. CCMEAN - Mean of 6 m canopy cover pixels intersecting plot
2. CCSTD - Standard deviation of 6 m canopy cover pixels intersecting plot
3. CCMIN - Minimum of 6 m canopy cover pixels intersecting plot
4. CCMAX - Maximum of 6 m canopy cover pixels intersecting plot

---

mostused

*Tabulate references most often used in imputation*

---

## Description

Provides a matrix of reference observations that are used most often as sources of imputation and a column of the counts. The observations are listed in sorted order, most often used first.

## Usage

```
mostused(object, n=20, kth=NULL)
```

## Arguments

object	(1) a data frame created by <code>foruse</code> , or (2) an object created by <code>yai</code> in which case <code>foruse</code> is called automatically.
n	the number of mostused in sorted order.
kth	passed to <code>foruse</code> , if called.

## Author(s)

Nicholas L. Crookston <ncrookston.fs@gmail.com>  
Andrew O. Finley <finleya@msu.edu>

## Examples

```
require(yaImpute)

data(iris)

# form some test data
refs=sample(rownames(iris),50)
x <- iris[,1:3]      # Sepal.Length Sepal.Width Petal.Length
y <- iris[refs,4:5] # Petal.Width Species

# build a yai object using mahalanobis
mal <- yai(x=x,y=y,method="mahalanobis")
```

```
mostused(mal, kth=1)
```

---

newtargets	<i>Finds K nearest neighbors for new target observations</i>
------------	--

---

### Description

Finds nearest neighbor *reference* observations for a given set of *target* observations using an established (see [yai](#)) object. Intended use is to facilitate breaking up large imputation problems (see [AsciiGridImpute](#)).

### Usage

```
newtargets(object, newdata, k=NULL, ann=NULL, nVec=NULL)
```

### Arguments

object	an object of class <a href="#">yai</a> .
newdata	a data frame or matrix of new <i>targets</i> for which neighbors are found. Must include at least the <i>X</i> -variables used in the original call to <a href="#">yai</a> .
k	if NULL, the value is taken from object, otherwise the number of nearest neighbors to find.
ann	if NULL, the value is taken from object. When TRUE <a href="#">ann</a> is used to find neighbors, and when FALSE a slow exact search is used.
nVec	If defined, specify the number of axes in the CCA

### Value

An object of class [yai](#), that is a copy of the first argument with the following elements replaced:

call	the call.
obsDropped	a list of the row names for observations dropped for various reasons (missing data).
trgRows	a list of the row names for target observations as a subset of all observations.
xall	the <i>X</i> -variables for all observations.
neiDstTrgs	a matrix of distances between a target (identified by its row name) and the <i>k</i> references. There are <i>k</i> columns.
neiIdsTrgs	a matrix of reference identifications that correspond to <code>neiDstTrgs</code> .
neiDstRefs	set NULL as if <code>noRefs=TRUE</code> in the original call to <a href="#">yai</a> .
neiIdsRefs	set NULL as if <code>noRefs=TRUE</code> in the original call to <a href="#">yai</a> .
k	the value of <i>k</i> , replaced if changed.
ann	the value of the <code>ann</code> argument.

**Examples**

```
require (yaImpute)

data(iris)

# set the random number seed so that example results are consistent
# normally, leave out this command
set.seed(12345)

# form some test data
refs=sample(rownames(iris),50) # just the reference observations
x <- iris[refs,1:3] # Sepal.Length Sepal.Width Petal.Length
y <- iris[refs,4:5] # Petal.Width Species

# build a yai object using mahalanobis
mal <- yai(x=x,y=y,method="mahalanobis")

# get imputations for the target observations (not references)
malNew <- newtargets(mal,iris[!(rownames(iris) %in% rownames(x)),])

# output a data frame of observed and imputed values for
# the observations that are not in the original yai object

impute(malNew,vars=yvars(malNew))

# in this example, Y is not specified (not required for mahalanobis).
mal2 <- yai(x=x,method="mahalanobis")
identical(foruse(mal),foruse(mal2))

if (require(randomForest))
{
  # here, method randomForest's unsupervised classification is used (no Y).
  rf <- yai(x=x,method="randomForest")
  # now get imputations for the targets in the iris data (those that are
  # not references).
  rfNew <- newtargets(rf,iris[!(rownames(iris) %in% rownames(x)),])
}
```

---

notablyDifferent	<i>Finds observations with large differences between observed and imputed values</i>
------------------	--

---

### Description

This routine identifies observations with large errors as measured by scaled root mean square error (see [rmsd.yai](#)). A *threshold* is used to detect observations with large differences.

### Usage

```
notablyDifferent(object, vars=NULL, threshold=NULL, p=.05, ...)
```

### Arguments

object	an object of class <a href="#">yai</a> .
vars	a vector of character strings naming the variables to use, if null the X-variables from object are used.
threshold	a threshold that if exceeded the observations are listed as <i>notably</i> different.
p	$(1-p)*100$ is the percentile point in the distribution of differences used to compute the threshold (used when threshold is NULL).
...	additional arguments passed to <a href="#">impute.yai</a> .

### Details

The scaled differences are computed as follows:

1. A matrix of differences between observed and imputed values is computed for each observation (rows) and each variable (columns).
2. These differences are scaled by dividing by the standard deviation of the observed values among the *reference* observations.
3. The scaled differences are squared.
4. Row means are computed resulting in one value for each observation.
5. The square root of each of these values is taken.

These values are Euclidean distances between the target observations and their nearest references as measured using specified variables. All the variables that are used must have observed and imputed values. Generally, this will be the X-variables and not the Y-variables.

When threshold is NULL, the function computes one using the [quantile](#) function with its default arguments and probs=1-p.

**Value**

A named list of several items. In all cases vectors are named using the observation ids which are the row names of the data used to build the `yai` object.

<code>call</code>	The call.
<code>vars</code>	The variables used (may be fewer than requested).
<code>threshold</code>	The threshold value.
<code>notablyDifferent.refs</code>	A sorted named vector of <i>references</i> that exceed the threshold.
<code>notablyDifferent.trgs</code>	A sorted named vector of <i>targets</i> that exceed the threshold.
<code>rmsdS.refs</code>	A sorted named vector of scaled RMSD <i>references</i> .
<code>rmsdS.trgs</code>	A sorted named vector of scaled RMSD <i>targets</i> .

msn <- yai(x=x,y=y2,method="msn")

notablyDifferent(msn)
```

---

notablyDistant	<i>Find notably distant targets</i>
----------------	-------------------------------------

---

### Description

Notably distant *targets* are those with relatively large distances from the closest *reference* observation. A suitable *threshold* is used to detect large distances.

### Usage

```
notablyDistant(object, kth=1, threshold=NULL, p=0.01, method="distribution")
```

### Arguments

object	an object of class <a href="#">yai</a> .
kth	the kth neighbor is used.
threshold	the threshold distance that identifies <i>notably</i> large distances between observations.
p	$(1-p)*100$ is the percentile point in the distribution of distances used to compute the threshold (only used when <i>threshold</i> is NULL).
method	the method used to compute the <i>threshold</i> , see details.

### Details

When *threshold* is NULL, the function computes one using one of two methods. When *method* is "distribution", assumption is made that distances follow the lognormal distribution, unless the method used to find neighbors is `randomForest`, in which case the distances are assumed to follow the beta distribution. A specified *p* value is used to compute the threshold, which is the point in the distribution where a fraction, *p*, of the neighbors are larger than the threshold.

When *method* is "quantile", the function uses the [quantile](#) function with `probs=1-p`.

### Value

List of two data frames that contain 1) the *references* that are notably distant from other *references*, 2) the *targets* that are notably distant from the *references*, 3) the *threshold* used, and 4) the *method* used.

```

---

plot.yai	<i>Plot observed verses imputed data</i>
----------	--

---

### Description

Provides a matrix of plots of observed verses imputed values for variables in an object created by `impute.yai`, which are of class `c("impute.yai", "data.frame")`.

### Usage

```
## S3 method for class 'yai'  
plot(x, vars=NULL, pointColor=1, lineColor=2, spineColor=NULL, residual=FALSE, ...)
```

### Arguments

x	1. a data frame created by <code>impute.yai</code> , or 2. an object created by <code>yai</code> .
vars	a list of variable names you want to include, if NULL all available Y-variables are included.
pointColor	a color vector for the xy plots (continuous variables).
lineColor	a color 1:1 lines in xy plots.
spineColor	a color vector for the spine plots (factors), one value per level.
residual	plots in a residual format (observed-imputed over imputed).
...	passed to called functions.

### Author(s)

Nicholas L. Crookston <ncrookston.fs@gmail.com>  
Andrew O. Finley <finleya@msu.edu>

### Examples

```
require(yaImpute)  
  
data(iris)  
  
# form some test data  
refs=sample(rownames(iris),50)  
x <- iris[,1:3]      # Sepal.Length Sepal.Width Petal.Length  
y <- iris[refs,4:5] # Petal.Width Species  
  
mal <- yai(x=x,y=y,method="mahalanobis")  
malImp=impute(mal,newdata=iris)  
plot(malImp)
```

---

`predict.yai`*Generic predict function for class yai*

---

**Description**

Provides a generic interface for getting predicted values for `yai` objects.

**Usage**

```
## S3 method for class 'yai'  
predict(object,newdata,...)
```

**Arguments**

<code>object</code>	an object of class <code>yai</code> which is passed as argument to <code>newtargets</code> , <code>impute.yai</code> , or both of these functions, see details.
<code>newdata</code>	a data frame that at a minimum contains the X-variables for new observations.
<code>...</code>	passed to <code>newtargets</code> and <code>impute.yai</code> , see details.

**Details**

When argument `newdata` is present function `newtargets` is called followed by a call to `impute.yai`. If include in the `...`, the arguments `k` and `ann` are passed to `newtargets`.

When argument `newdata` is absent, `impute.yai` is called without first calling `newtargets`.

All of the `...` arguments are passed to `impute.yai`.

Another form of prediction in imputation is to get the identity of the imputed observations. Use function `foruse` for this purpose.

**Value**

An object of class `impute.yai`.

**Author(s)**

Nicholas L. Crookston <ncrookston.fs@gmail.com>

**See Also**

`foruse`, `newtargets` `impute.yai`

print.yai	<i>Print a summary of a yai object</i>
-----------	--

---

**Description**

Provides a summary of a [yai](#) object, showing the call and essential data customized for each method used.

**Usage**

```
## S3 method for class 'yai'
print(x,...)
```

**Arguments**

x	an object of class yai.
...	not used

**Author(s)**

Nicholas L. Crookston <ncrookston.fs@gmail.com>  
Andrew O. Finley <finleya@msu.edu>

---

rmsd.yai	<i>Root Mean Square Difference between observed and imputed</i>
----------	---

---

**Description**

Computes the root mean square difference (RMSD) between observed and imputed values for each observation that has both. RMSD is computationally like RMSE, but they differ in interpretation. The RMSD values can be scaled to afford comparisons among variables.

**Usage**

```
rmsd.yai (object, vars=NULL, scale=FALSE, ...)
```

**Arguments**

object	an object created by <a href="#">yai</a> or <a href="#">impute.yai</a>
vars	a list of variable names you want to include, if NULL all available variables are included
scale	when TRUE, the values are scaled (see details), if a named vector, the values are scaled by the corresponding values.
...	passed to called methods, very useful for passing argument ancillaryData to function <a href="#">impute.yai</a>

### Details

By default, RMSD is computed using standard formula for its related statistic, RMSE. When `scale=TRUE`, or set of values is supplied, RMSD is divided by the scaling factor. The scaling factor is the standard deviation of the *reference* observations under the assumption that they are representative of the population.

### Value

A data frame with the row names as vars and the column as `rmsd`. When `scale=TRUE`, the column name is `rmsdS`. The scaling factors used, if any, are returned as an attribute.

### Author(s)

Nicholas L. Crookston <[ncrookston.fs@gmail.com](mailto:ncrookston.fs@gmail.com)>

---

TallyLake

*Tally Lake, Flathead National Forest, Montana, USA*

---

### Description

Polygon-based reference data used by Stage and Crookston (2007) to demonstrate partitioning of error components and related statistics. Observations are summaries of data collected on forest stands (ploysgons).

### Usage

```
data(TallyLake)
```

### Format

A data frame with 847 rows and 29 columns:

Ground based measurements of trees (Y-variables):

1. TopHt - Height of tallest trees (ft)
2. LnVolL - Log of the volume ( $ft^3/acre$ ) of western larch
3. LnVolDF - Log of the volume ( $ft^3/acre$ ) of Douglas-fir
4. LnVolLP - Log of the volume ( $ft^3/acre$ ) of lodgepole pine
5. LnVolES - Log of the volume ( $ft^3/acre$ ) of Engelmann spruce
6. LnVolAF - Log of the volume ( $ft^3/acre$ ) of alpine fir
7. LnVolPP - Log of the volume ( $ft^3/acre$ ) of ponderosa pine

8. CCover - Canopy cover (percent)

Geographic Location, Slope, and Aspect (X-variables):

1. utmx - UTM easting at plot center
2. utmy - UTM northing at plot center
3. elevm - Mean elevation (ft) above sea level over plot
4. eevsqrd -  $(elevm - 1600)^2$
5. slopem - Mean slope (percent) over plot
6. slpcosaspm - Mean of slope (proportion) times the cosine of aspect (see Stage (1976) for description of this transformation)
7. slpsinaspm - Mean of slope (proportion) times the sine of aspect

Additional X-variables:

1. ctim - Mean of slope curvature over pixels in stand
2. tmb1m - Mean of LandSat band 1 over pixels in stand
3. tmb2m - Mean of LandSat band 2 over pixels in stand
4. tmb3m - Mean of LandSat band 3 over pixels in stand
5. tmb4m - Mean of LandSat band 4 over pixels in stand
6. tmb5m - Mean of LandSat band 5 over pixels in stand
7. tmb6m - Mean of LandSat band 6 over pixels in stand
8. durm - Mean of light duration over pixels in stand
9. insom - Mean of solar insolation over pixels in stand
10. msavim - Mean of AVI for pixels in stand
11. ndvim - Mean of NDVI for pixels in stand
12. crvm - Mean of slope curvature for pixels in stand
13. tancrvm - Mean of tangent curvature for pixels in stand
14. tancrvsd - Standard deviation of tangent curvature for pixels in stand

unionDataJoin	<i>Combines data from several sources</i>
---------------	---

---

### Description

Takes any combination of several data frames or matrices and creates a new data frame. The rows are defined by a union of all row names in the arguments, and the columns are defined by a union of all column names in the arguments. The data are loaded into this new frame where column and row names match the individual inputs. Duplicates are tolerated with the last one specified being the one kept. NAs are returned for combinations of rows and columns where no data exist. Factors are processed as necessary.

### Usage

```
unionDataJoin(..., warn=TRUE)
```

### Arguments

... a list of data frames, matrices, or any combination.  
 warn when TRUE, warn when a column name is found in more than one data source.

### Value

A data frame.

### Author(s)

Nicholas L. Crookston <ncrookston.fs@gmail.com>  
 Andrew O. Finley <finleya@msu.edu>

### Examples

```
require(yaImpute)

d1=data.frame(x1=c("a", "b", "c", "d", "e", "f"))
d2=data.frame(x1=as.character(seq(1,4)), row.names=seq(5,8))
d3=data.frame(x2=seq(1:10))

# note the levels
levels(d1$x1)
# [1] "a" "b" "c" "d" "e" "f"

levels(d2$x1)
# [1] "1" "2" "3" "4"

all=unionDataJoin(d1,d2,d3, warn=FALSE)
all
#      x1 x2
# 1     a  1
```

```
# 2    b  2
# 3    c  3
# 4    d  4
# 5    1  5
# 6    2  6
# 7    3  7
# 8    4  8
# 9 <NA> 9
# 10 <NA> 10

levels(all$x1)
# [1] "1" "2" "3" "4" "a" "b" "c" "d"
```

---

vars *List variables in a yai object*

---

### Description

Provides a character vector, or a list of character vectors of all the variables in a [yai](#) object, just the X-variables (xvars), or just the Y-variables (yvars).

### Usage

```
vars(object)
xvars(object)
yvars(object)
```

### Arguments

object            an object created by [yai](#).

### Value

yvars            A character vector of Y-variables.  
xvars            A character vector of X-variables.  
vars             A list of both vectors.

### Author(s)

Nicholas L. Crookston <ncrookston.fs@gmail.com>  
Andrew O. Finley <finleya@msu.edu>

### See Also

[yai](#)

varSelection

*Select variables for imputation models***Description**

Computes [grmsd](#) (generalized root mean square distance) as variables are added to (method="addVars") or removed from (method="delVars") an k-NN imputation model. When adding variables the function keeps variables that strengthen imputation and deletes that weaken the imputation the least. The measure of model strength is grmsd between imputed and observed *Y*-variables among the reference observations.

**Usage**

```
varSelection(x,y,method="addVars",yaiMethod="msn",imputeMethod="closest",
  wts=NULL,nboot=20,trace=FALSE,
  useParallel=if (.Platform$OS.type == "windows") FALSE else TRUE,...)
```

**Arguments**

x	a set of <i>X</i> -Variables as used in <a href="#">yai</a> .
y	a set of <i>Y</i> -Variables as used in <a href="#">yai</a> .
method	if addVars, the X-Variables are added and if delVars they are deleted (see details).
yaiMethod	passed as method to <a href="#">yai</a> .
imputeMethod	passed as method to <a href="#">impute.yai</a> .
wts	passed as argument wts to <a href="#">grmsd</a> which is used to score the alternative variable sets.
nboot	the number of bootstrap samples used at each variable selection step (see Details). When nboot is zero, NO bootstrapping is done.
trace	if TRUE information at each step is output.
useParallel	function <code>link{parallel:mclapply}</code> from <b>parallel</b> will be used if it is available for running the bootstraps. If it is not available, <code>link{lapply}</code> is used (which is the only option on windows).
...	passed to <code>link{yai}</code>

**Details**

This function tracks the effect on generalized root mean square distance (see [grmsd](#)) when variables are added or deleted one at a time. When adding variables, the function starts with none, and keeps the single variable that provides the smallest grmsd. When deleting variables, the function starts with all *X*-Variables and deletes them one at a time such that those that remain provide the smallest grmsd. The function uses the following steps:

1. Function `yai` is run for all the Y-variables and candidate X-variable(s). The result is passed to `impute.yai` to get imputed values of Y-variables. That result is passed to `grmsd` to compute a mean Mahalanobis distance for the case where the candidate variable is included (or deleted depending on method). However, these steps are done once for each bootstrap replication and the resulting values are averaged to provide an average mean Mahalanobis distance over the bootstraps.
2. Step one is done for each candidate X-variable forming a vector of `grmsd` values, one corresponding to the case where each candidate is added or deleted.
3. When variables are being added (method="addVars"), the variable that is related to the smallest `grmsd` is kept. When variables are being deleted (method="delVars"), the variable that is related to the largest `grmsd` is deleted.
4. Once a variable has been added or deleted, the function proceeds to select another variable for selection or deletion by considering all remaining variables.

### Value

An list of class `varSel` with these tags:

<code>call</code>	the call
<code>grmsd</code>	a 2-column matrix of the mean and std dev of the mean Mahalanobis distances associated with adding or removing the variables stored as the rownames. When <code>nboot&lt;2</code> , the std dev are NA
<code>allgrmsd</code>	a list of the <code>grmsd</code> values that correspond to each bootstrap replication. The data in <code>grmsd</code> are based on these vectors of information.
<code>method</code>	the value of argument <code>method</code> .

### Examples

```
data(iris)

set.seed(12345)

x <- iris[,1:2] # Sepal.Length Sepal.Width
y <- iris[,3:4] # Petal.Length Petal.Width

vsel <- varSelection(x=x,y=y,nboot=5,useParallel=FALSE)
vsel

bestVars(vsel)
```

```
plot(vsel)
```

---

whatsMax	<i>Find maximum column for each row</i>
----------	---

---

### Description

For each row, the function identifies the column that has the maximum value. The function returns a data frame with two columns: the first is the column name corresponding to the column of maximum value and the second is the correspond maximum. The first column is converted to a factor.

If the maximum is zero, the maximum column is identified as "zero".

If there are over nbig factors in column 1, the maximum values that are less than the largest are combined and identified as "other".

Intended use is to transform community ecology data for use in [yai](#) where method is *randomForest*.

### Usage

```
whatsMax(x, nbig=30)
```

### Arguments

x	a data frame or matrix of numeric values.
nbig	see description—the maximum number of factors, the remainder called 'other'.

### Value

A data frame.

### Author(s)

Nicholas L. Crookston <ncrookston.fs@gmail.com>  
Andrew O. Finley <finleya@msu.edu>

### Examples

```
data(MoscowMtStJoe)

# get the basal area by species columns
yba <- MoscowMtStJoe[,1:17]

# for each row, pick the species that has the max basal area
# create "other" for those not in the top 7.

ybaB <- whatsMax(yba, nbig=7)
levels(ybaB[,1])
```

yai

*Find K nearest neighbors***Description**

Given a set of observations, yai

1. separates the observations into *reference* and *target* observations,
2. applies the specified method to project X-variables into a Euclidean space (not always, see argument method), and
3. finds the *k*-nearest neighbors within the reference observations and between the reference and target observations.

An alternative method using [randomForest](#) classification and regression trees is provided for steps 2 and 3. *Target* observations are those with values for X-variables and not for Y-variables, while *reference* observations are those with no missing values for X-and Y-variables (see Details for the exception).

**Usage**

```
yai(x=NULL,y=NULL,data=NULL,k=1,noTrgs=FALSE,noRefs=FALSE,
    nVec=NULL,pVal=.05,method="msn",ann=TRUE,mtry=NULL,ntree=500,
    rfMode="buildClasses",bootstrap=FALSE,ppControl=NULL,sampleVars=NULL,
    rfXsubsets=NULL,oob=FALSE)
```

**Arguments**

x	1) a matrix or data frame containing the X-variables for all observations with row names are the identification for the observations, or 2) a one-sided formula defining the X-variables as a linear formula. If a formula is coded for x, one must be used for y as well, if needed.
y	1) a matrix or data frame containing the Y-variables for the reference observations, or 2) a one-sided formula defining the Y-variables as a linear formula.
data	when x and y are formulas, then data is a data frame or matrix that contains all the variables with row names are the identification for the observations. The observations are split by yai into two sets.
k	the number of nearest neighbors; default is 1.
noTrgs	when TRUE, skip finding neighbors for target observations.
noRefs	when TRUE, skip finding neighbors for reference observations.
nVec	number of canonical vectors to use (methods msn and msn2), or number of independent of X-variables reference data when method mahalanobis. When NULL, the number is set by the function.
pVal	significant level for canonical vectors, used when method is msn or msn2.
method	is the strategy used for computing distance and therefore for finding neighbors; the options are quoted key words (see details):

1. euclidean - distance is computed in a normalized X space.
2. raw - like euclidean, except no normalization is done.
3. mahalanobis - distance is computed in its namesakes space.
4. ica - like mahalanobis, but based on *Independent Component Analysis* using package [fastICA](#).
5. msn - distance is computed in a projected canonical space.
6. msn2 - like msn, but with variance weighting (canonical regression rather than correlation).
7. msnPP - like msn, except that the canonical correlation is computed using projection pursuit from **ccaPP** (see argument `ppControl`).
8. gnn - distance is computed using a projected ordination of Xs found using canonical correspondence analysis ([cca](#) from package **vegan**). If [cca](#) fails, [rda](#) is used and a warning is issued.
9. randomForest - distance is one minus the proportion of **randomForest** trees where a target observation is in the same terminal node as a reference observation (see [randomForest](#)).
10. random - like raw except that the X space is a single vector of uniform random [0,1] numbers generated using [runif](#), results in random assignment of neighbors, and forces `ann` to be FALSE.
11. gower - distance is computed in its namesakes space using function [gower\\_topn](#) from package **gower**; forces `ann` to be FALSE.

<code>ann</code>	TRUE if <code>ann</code> is used to find neighbors, FALSE if a slow search is used.
<code>mtry</code>	the number of X-variables picked at random when method is <code>randomForest</code> , see <a href="#">randomForest</a> , default is <code>sqrt(number of X-variables)</code> .
<code>ntree</code>	the number of classification and regression trees when method is <code>randomForest</code> . When more than one Y-variable is used, the trees are divided among the variables. Alternatively, <code>ntree</code> can be a vector of values corresponding to each Y-variable.
<code>rfMode</code>	when <code>buildClasses</code> and method is <code>randomForest</code> , continuous variables are internally converted to classes forcing <code>randomForest</code> to build classification trees for the variable. Otherwise, regression trees are built if your version of <b>randomForest</b> is newer than 4.5-18.
<code>bootstrap</code>	if TRUE, the reference observations are sampled with replacement.
<code>ppControl</code>	used to control how canonical correlation analysis via projection pursuit is done, see <a href="#">Details</a> .
<code>sampleVars</code>	the X- and/or Y-variables will be sampled (without replacement) if this is not NULL and greater than zero. If specified as a single unnamed value, that value is used to control the sample size of both X and Y variables. If two unnamed values, then the first is taken for X-variables and the second for Y-variables. If zero, no sampling is done. Otherwise, values are less than 1.0 they are taken as the proportion of the number of variables. Values greater or equal to 1 are number of variables to be included in the sample. Specification of a large number will cause the sequence of variables to be randomized.
<code>rfXsubsets</code>	a named list of character vectors where there is one vector for each Y-variable, see <a href="#">details</a> , only applies when <code>method="randomForest"</code>

oob Boolean when TRUE keep OOB in randomForest models, default FALSE. This is useful for calculating out-of-bag evaluation statistics for the models method="randomForest"

## Details

See the paper at [doi:10.18637/jss.v023.i10](https://doi.org/10.18637/jss.v023.i10) (it includes examples).

The following information is in addition to the content in the papers.

You need not have any Y-variables to run yai for the following methods: euclidean, raw, mahalanobis, ica, random, and randomForest (in which case unsupervised classification is performed). However, normally yai classifies *reference* observations as those with no missing values for X- and Y- variables and *target* observations are those with values for X- variables and missing data for Y-variables. When Y is NULL (there are no Y-variables), all the observations are considered *references*. See [newtargets](#) for an example of how to use yai in this situation.

When bootstrap=TRUE the reference observations are sampled with replacement. The sample size is set to the number of reference observations. Normally, about a third of the reference observations are left out of the sample; they are often called out-of-bag samples. The out-of-bag observations are then treated as targets.

When method="msnPP" projection pursuit from **ccaPP** is used. The method is further controlled using argument ppControl to specify a character vector that has two named components.

1. method - One of the following "spearman", "kendall", "quadrant", "M", "pearson", default is "spearman"
2. searc - If "data" or "proj", then [ccaProj](#) is used, otherwise the default [ccaGrid](#) is used.

Here are some details on argument rfXsubsets. When method="randomForest" one call to [randomForest](#) is generated for each Y-variable. When argument rfXsubsets is left NULL, all the X-variables are used for each of the Y-variables. However, sometimes better results can be achieved by using specific subsets of X-variables for each Y-variable. This is done by setting rfXsubsets equal to a named list of character vectors. The names correspond to the Y-variable names and the character vectors hold the list of X-variables for the corresponding Y-variable.

## Value

An object of class yai, which is a list with the following tags:

call	the call.
yRefs, xRefs	matrices of the X- and Y-variables for just the reference observations (unscaled). The scale factors are attached as attributes.
obsDropped	a list of the row names for observations dropped for various reasons (missing data).
trgRows	a list of the row names for target observations as a subset of all observations.
xall	the X-variables for all observations.
cancor	returned from cancor function when method msn or msn2 is used (NULL otherwise).
ccaVegan	an object of class cca (from package <b>vegan</b> ) when method <i>gmn</i> is used.

<code>fTest</code>	a list containing partial F statistics and a vector of $Pr>F$ (pgf) corresponding to the canonical correlation coefficients when method <code>msn</code> or <code>msn2</code> is used (NULL otherwise).
<code>yScale, xScale</code>	scale data used on <code>yRefs</code> and <code>xRefs</code> as needed.
<code>k</code>	the value of $k$ .
<code>pVal</code>	as input; only used when method <code>msn</code> , <code>msn2</code> or <code>msnPP</code> is used.
<code>projector</code>	NULL when not used. For methods <code>msn</code> , <code>msn2</code> , <code>msnPP</code> , <code>gnn</code> and <code>mahalanobis</code> , this is a matrix that projects normalized X-variables into a space suitable for doing Eculidian distances.
<code>nVec</code>	number of canonical vectors used (methods <code>msn</code> and <code>msn2</code> ), or number of independent X-variables in the reference data when method <code>mahalanobis</code> is used.
<code>method</code>	as input, the method used.
<code>ranForest</code>	a list of the forests if method <code>randomForest</code> is used. There is one forest for each Y-variable, or just one forest when there are no Y-variables.
<code>ICA</code>	a list of information from <code>fastICA</code> when method <code>ica</code> is used.
<code>ann</code>	the value of <code>ann</code> , TRUE when <code>ann</code> is used, FALSE otherwise.
<code>xlevels</code>	NULL if no factors are used as predictors; otherwise a list of predictors that have factors and their levels (see <code>lm</code> ).
<code>neiDstTrgs</code>	a matrix of distances between a target (identified by its row name) and the $k$ references. There are $k$ columns.
<code>neiIdsTrgs</code>	a matrix of reference identifications that correspond to <code>neiDstTrgs</code> .
<code>neiDstRefs, neiIdsRefs</code>	counterparts for references.
<code>bootstrap</code>	a vector of reference rownames that constitute the bootstrap sample; or the value FALSE when bootstrap is not used.

---

yaiRFsummary

*Build Summary Data For Method RandomForest*

---

### Description

When method `randomforest` is used to build a `yai` object, the `randomForest` package computes several statistics. This function summarizes some of them, including the variable importance scores computed by function `yaiVarImp`.

### Usage

```
yaiRFsummary(object, nTop=0)
```

### Arguments

<code>object</code>	an object of class <code>yai</code> .
<code>nTop</code>	the <code>nTop</code> most important variables are plotted (returned).

### Value

A list containing:

`forestAttributes`

a data frame reporting the error rates and other data from the `randomForest(s)`.

`scaledImportance`

the data frame computed by `yaiVarImp`.

**Author(s)**

Nicholas L. Crookston <ncrookston.fs@gmail.com>  
Andrew O. Finley <finleya@msu.edu>

**See Also**

---

yaiVarImp

*Reports or plots importance scores for yai method randomForest*

---

**Description**

When method `randomforest` is used to build a `yai` object, the `randomForest` package computes variable importance scores. This function computes a composite of the scores and scales them using `scale`. By default the scores are plotted and scores themselves are invisibly returned. For classification, the scores are derived from "MeanDecreaseAccuracy" and for regression they are based in " using `importance`.

**Usage**

```
yaiVarImp(object, nTop=20, plot=TRUE, ...)
```

**Arguments**

<code>object</code>	an object of class <code>yai</code>
<code>nTop</code>	the <code>nTop</code> most important variables are plotted (returned); if NA or zero, all are returned
<code>plot</code>	if FALSE, no plotting is done, but the scores are returned.
<code>...</code>	passed to the <code>boxplot</code> function.

**Value**

A data frame with the rows corresponding to the `randomForest` built for each *Y*-variable and the columns corresponding to the `nTop` most important *Y*-variables in sorted order.

**Author(s)**

Nicholas L. Crookston <ncrookston.fs@gmail.com>
